Abstract

In this article, we present the Mocha wide area computing infrastructure we are currently developing. Mocha provides support for robust shared objects on heterogeneous platforms, and utilizes advanced distributed shared memory techniques for maintaining consistency of shared objects that are replicated at multiple nodes to improve performance. In addition, our system handles failures that we feel will be common in wide area environments. For example, to ensure that the state of an object is not lost due to a node failure, updated state of the object can be disseminated to several other nodes. The overhead of such state dissemination can be controlled based on the level of availability needed for shared objects. We have used an approach that makes use of multiple communication protocols to improve the efficiency of shared object state transfers in Mocha. We also provide an empirical evaluation of our prototype implementation for both local and wide area networks and present a sample home service application written with the system.

1 Introduction

The growth in popularity of the World Wide Web (WWW) has resulted in the development of a new generation of tools tailored to Internet computing activities. Prominent examples include the Java programming language and Java capable Web browsers. These Web spinoffs are having a profound impact on the field of distributed computing. Whereas distributed computing has traditionally focused on improving the functionality of local clusters of computers, technology is progressing such that wide area computing networks are now becoming a popular target environment for research in distributed computing.

With wide area distributed computing environments, geographically distributed resources such as workstations, personal computers, supercomputers, graphic rendering engines, and scientific instruments will be available for use in a seamless fashion by parallel applications[GW96, FGKT96]. Many envision that it will be possible to transport application code to remote sites in the wide area virtual computer where it may be executed in the presence of needed resources. The area of research devoted to bringing this vision to reality in the context of scientific applications is referred to as *metacomputing*. A metacomputing system is the software infrastructure which orchestrates collections of hosts and networks into functioning as a large virtual computer for use by parallel and distributed applications.

Metacomputing environments are useful for a variety of distributed and parallel applications, particularly those which need access to remote resources (e.g. data from a remote microscope) or applications that are able to effectively utilize a substantial number of computing resources that the Internet may easily provide. Moreover, other wide area distributed computing domains such as electronic commerce applications (e.g. service to the home), which require more advanced capabilities than those provided by a standard web browser, could also benefit from advances made in wide area distributed computing.

Wide area computing environments have several salient differences from traditional local area network computing environments. For example, there is less autonomy and control over resources (e.g. workstations) as many of the resources are remotely located and controlled by others. Furthermore, failures in a wide area computing environment are a relatively common occurrence. Failures, when detected by timeout mechanisms, result from network congestion and varying workloads at nodes. Also, the autonomy of nodes can result in a remote node reboot or the owner of such a node can choose to terminate foreign tasks.

There are many problems that need to be solved to enable wide area applications to become common. One important issue that we address here is a robust shared object model for wide area applications. Because these applications are themselves distributed applications, they are dependent on some mechanism for sharing state across workstations to allow processors to cooperatively work together. The shared memory and shared object models are attractive for state sharing because they are simpler to program than standard message passing. They have been explored in [KCZ92, BZ91, GLL+90, BK93]. Our focus is on providing efficient state sharing that is integrated with failure handling support.

The following are the contributions of our work in robust state sharing for a wide area computing environment:

- The Mocha system, which is a wide area computing infrastructure that provides basic facilities such as remote evaluation support, security, debugging support, and a highly scalable thread-safe network communication library.
- The design of a "multiple protocol" approach which combines the capabilities of Mocha's network library and the TCP protocol to support efficient transfer of object replicas in a scalable fashion.
- Support for shared objects on heterogeneous platforms. To improve performance and mitigate communication latencies, copies of objects can be created and accessed locally.
- Object sharing support that utilizes advanced distributed shared memory techniques for maintaining consistency of shared objects.
- Fault tolerance support that allows its overhead to be controlled based on the level of availability needed by an application for its objects.
- Empirical evaluation of the system in both local and wide area networks.

The following section provides an overview of Mocha and includes a description of its user interface as well as its shared object model. An overview of Mocha's support software, with an emphasis on basic algorithms and key implementation features, follows. Next, failure handling refinements are presented. We also present a performance evaluation of Mocha's state sharing capabilities. Related work is then discussed and the concluding section reports on ongoing and future work.

2 Mocha Overview

To motivate the need for a framework such as Mocha, we begin with a description of a potential wide area distributed application. Consider an application in which a consumer at home wishes to add a new formal dinner table place setting composed of flatware, plates, and glassware. At the consumer's home, a graphical user interface is executing which allows various flatware, plates, and glassware to be viewed together so that the consumer may "mix and match" these items and end up with a pleasing coordinated table setting. Additionally, a sales associate located at the retail outlet may also have a copy of the graphical user interface which permits the associate to see what the customer is selecting and may suggest alternatives which are then presented in the customer's GUI. Furthermore, the home consumer may have requested friends located at other homes to also participate in this decision making and therefore they too may be running a GUI and viewing the possibilities and also making suggestions. In this scenario, it is expected that the platforms on which the GUI executes in each of the homes would be vastly different from the platform at the retail outlet.

For a wide area computing infrastructure to support the above scenario, there are several features it must provide. First, it must provide support for shipping platform independent GUI code to the remote sites and allow the code to execute in a secure environment. Second, the infrastructure must provide support that allows the GUI's to share objects among each of the sites. Finally, the infrastructure must enable applications to be written such that they are resilient to failures at some of the remote sites.

The Mocha system is capable of supporting an application scenario such as the one described above. It is written entirely in Java and provides the application programmer with a framework for developing wide area distributed applications in the Java language. In addition to providing constructs for distributed computing such as the remote spawning of threads and state sharing between these threads, the Mocha system provides features that enable it to serve as a wide-area computing environment. These include security, the ability to ship and dynamically link in application code (i.e., remote evaluation support[SG90]), and basic debugging and event logging facilities that provide insight into execution of code at remote locations.

In order to start a distributed application, Mocha assumes that at each site that wishes to participate in the execution of the distributed application (i.e., a workstation or Java capable PC), someone will startup one of its *Site Managers* which listens on a well known port. The *Site Manager* listens on this port for requests to utilize the workstation and is responsible for controlling the number of true processes on the workstation that are allocated for use by remote tasks. These processes are referred to as *Mocha Servers* because they are able to "serve" a thread executing on behalf of a remote task with anything it may need. For example, a *Mocha Server* provides a thread with the ability to receive and link in more application code, as well as other features such as communicating results and reporting error conditions.

Mocha's basic constructs for distributed computing are fashioned after constructs for popular local area distributed computing environments such as PVM[Sun90]. However, the primitives have been modified to take advantage of Java's object oriented capabilities.

In the Mocha environment, the application is composed of threads which execute in the address spaces of Mocha Servers. These threads may be initiated (i.e., spawned) using a method from the provided `Mocha` class. A typical section of code executed by a thread to spawn another Mocha thread is shown in Figure 1. When a new instance of the Mocha object is created, a hostfile is read which provides a list of potential sites at which remote threads may be spawned. The Mocha system provides a tool to generate this host file. As shown in the code fragment, a `Parameter` object is utilized for organizing the parameters that will eventually be sent to a remotely spawned thread. The actual spawn is performed by calling the `spawn()` method of class `Mocha` with the name of the Mocha thread class that is to be spawned and the `Parameter` object that is to be sent to remotely instantiated thread. Other spawn methods are available which allow the application to specify the exact host in the host file on which a remote thread should execute. In Figure 1, the class being spawned as a thread is the "Myhello" class. This and other classes that are intended to be spawned are provided by the application programmer.

```
import mocha.*;
public class TestMocha  {

   public static void main(String args[]) {
      Mocha mocha;
      ResultHandle rh;
      Parameter p;

      mocha = new Mocha();
      p = new Parameter();
      p.add("param1", 5);           // create parameters to
                                    // send to remotely evaluated class

      rh = mocha.spawn("Myhello", p); // spawn class named Myhello
                                      // remote site requests other
                                      // classes as necessary

   }
}
```

Figure 1: Mocha application code that spawns a class for remote evaluation.

In contrast to a spawn performed by a network computing environment such as PVM, Mocha's spawn provides remote evaluation support which allows it to transport and dynamically link in thread code at a remote Mocha server as necessary. Mocha's model for remote evaluation is that of an initial "push" of application code followed by "demand pulling" of new application code object classes as they are encountered during execution. The Mocha system relies upon its own communication substrate to perform this transmission.

Mocha threads may be derived from any Java class that implements the `MochaTask` interface. Through this interface the Mocha runtime is able to provide the application thread with a `Mocha` object that is essentially a "travel bag". The `Mocha` object currently provides a `Parameter` object from which the remotely evaluated task may retrieve the initial execution parameters denoted in the `spawn()` method that started this task. Also provided is a `Result` object in which the task may place results. Additionally, the `Mocha` object provides a variety of useful objects and methods that support remote printing, remote stack dumps, support for making replicated object copies and accessing the replicas, and enables a thread to recursively spawn other wide area computing threads. Figure 2 shows an example user class that utilizes the `Mocha` class to acquire initial startup parameters, perform remote printing and stack dumps, and then return its subresult. In this example, `Myhello` is a user class that has been written in a fashion that permits it to be shipped and executed at a remote site. After the class is shipped, the Mocha runtime creates a new thread that begins executing at the `mochastart()` method. The Mocha runtime provides this thread with a `Mocha` object from which the thread may invoke the travel bag related activities described above.

```
import mocha.*;
import java.lang.*;

public class Myhello implements MochaTask {
  public Myhello() {
  }
  public void mochastart(Mocha mocha) {
    double start=0.0, sum = 0.0;
    try {
      start = mocha.parameter.getdouble("start");
      sum = start + 1;

      mocha.mochaPrintln ("Returning as a return value " + sum);
      mocha.result.add("returnvalue", sum);
      mocha.returnResults();

    } catch (MochaParameterException e) {
      mocha.mochaPrintStackTrace(e);
    } catch (Throwable t) {
      mocha.mochaPrintStackTrace(t);
    }
  }
}
```

Figure 2: Remotely evaluated user class that illustrates the use of the Mocha object.

2.1 Mocha's Shared Object Model

Mocha's shared object model permits threads in separate Mocha Servers to share state. The primary goals of the model are (i) to provide an efficient scheme for the consistency maintenance of shared state between threads across Mocha servers running at different nodes and (ii) support the sharing of complex objects.

2.1.1 Maintaining Shared State Consistency

Mocha's model for maintaining shared state is motivated by weakly ordered shared memory models such as Release Consistency[GLL+90], Lazy Release Consistency[KCZ92], and Entry Consistency[BZ91]. These models have been shown to provide highly efficient state sharing implementations. In these memory models, shared memory is guarded by synchronization constructs (i.e., lock acquire and release) and is only made consistent with the most recent updates when certain synchronization points in the code are reached. Thus, in these models the shared memory may only be properly accessed between lock acquire and release synchronization points. This approach towards maintaining consistency has been shown to reach performance levels that are comparable to message passing models and thus is a very strong starting point for Mocha's shared object model.

Mocha's shared object model consists of `Replica` and `ReplicaLock` objects. All objects that are desired to be shared in the Mocha system must be of type Replica or subclass from it. Replicas are not required to represent a fixed size of data; the amount of shared data contained in a Replica may grow and shrink as the needs of the Replica vary during application execution. Replicas may contain both homogeneous arrays of primitive data types as well as bona fide Java objects which are serializable[R+96]. A

thread that wishes to create a shared object might use the following section of code:

```
int myarray[] = new int[10];
Replica replica1 = new Replica ("flatwareIndex", mocha, myarray, 5);
```

Here, the Replica constructor utilizes methods in the Mocha object to create a shared object that is an array of integers, will have 5 replicas, and is identified by the string *flatwareIndex*. Threads that wish to acquire replicas of this object would use a similar constructor:

```
Replica replica1 = new Replica ("flatwareIndex", mocha);
```

Here it is not necessary to denote what type of shared object the replica refers to for this information is already known by the Mocha runtime. For programming purposes, the Replica class provides signature methods that enable the application to determine the type and amount of data the Replica represents.

In their generic form, Replica objects enable the Mocha system to replicate or *publish* shared data at either all or a subset of cooperating Mocha threads. Since multiple nodes share Replica objects, in order for such objects to serve in a manner that resembles a shared object, each Replica must be *associated* with a `ReplicaLock` object. This association is exploited to efficiently maintain consistency guarantees between Replicas. This approach allows Mocha's runtime to exploit the synchronization present in an application to improve the performance of consistency maintenance, a technique well established by advanced DSM systems[BZ91, KCZ92]. Figure 3 shows a typical section of code in which Replicas are associated with a ReplicaLock to enable them to serve as a form of consistent distributed shared memory. These type of Replicas could be used in the service to the home table setting coordinator application described earlier in this section. In this example, several shared index Replicas are provided. These shared objects would be utilized to control which images of the retail items are presented at the same time. A String object is also provided to allow the users of the GUI's to send comments to each other. As shown in Figure 3, these Replicas are associated with a ReplicaLock. Once the ReplicaLock's `lock()` method returns, the lock has been acquired and the Replicas are consistent. At this point the Replicas may be accessed and modified as desired. The ReplicaLock may then be released via the `unlock()` method.

2.1.2 Supporting General Purpose Java Objects

By themselves, Mocha's Replica objects are able to store homogeneous arrays of Java's primitive data types such as `byte`, `int`, or `double`. However, it is expected that many applications may desire to share more complex objects that are either user defined or those provided by Java itself. Examples of the latter include `java.util.Date`, `java.util.Hashtable`, *etc.* These objects are more complicated to support as shared objects because they must be serialized into a byte array to enable them to be transported over the network. Java provides an object serialization package that greatly simplifies the process of serializing these objects. Typically, only a few lines of user

```
...

int intarray[] = new int[5];
String string = new String("Hello World");

Replica replica1 = new Replica ("flatwareIndex", mocha,  intarray, 5);
Replica replica2 = new Replica ("plateIndex", mocha, intarray, 5);
Replica replica3 = new Replica ("glasswareIndex", mocha, intarray, 5);

// The following is a generated subclass of Replica used for sharing
// a Java String,  a general purpose object.
StringReplica replica4 = new StringReplica ("text", mocha, string, 5);

// need to create a ReplicaLock
ReplicaLock rlock1 = new ReplicaLock( 1, mocha);

// associate Replicas with lock
rlock1.associate(replica1);
rlock1.associate(replica2);
rlock1.associate(replica3);

rlock1.lock();  // Lock must be acquired and Replicas are
                // made consistent before proceeding

// Replicas may now be accessed or updated in a consistent manner
replica1.intdata[0] = 1;
replica2.intdata[0] = 1;
replica3.intdata[0] = 1;
replica4.string  = "Good Choice";
rlock1.unlock();  // Lock is now released

...
```

Figure 3: Associating and locking shared object Replicas.

code are required to serialize or unserialize an object. With object serialization available, the only difficulty is to guarantee that objects are serialized before they may be sent to another thread and then unserialized when the update of the remote replica is performed.

Mocha supports the above functionality by allowing users to subclass from the standard Replica object and add a user specific complex object to the derived class as the object to be shared. Two methods are provided in Replica that may be overloaded in the derived class with serialization and unserialization code appropriate for the complex object that is desired to be shared. The Mocha runtime will automatically call these methods when it needs to marshal or unmarshal these shared objects. While creating a derived class and inserting the appropriate serialization/unserialization code into the overloaded methods is quite straightforward, it would nonetheless require extra coding effort from the application developer. To prevent this, a tool, `MochaGen`, is provided which generates a custom subclass of Replica which contains the object the user desires to share as well as a new custom constructor and the appropriate serialization/unserialization methods. Figure 4 presents skeleton code for `StringReplica`, a generated subclass of Replica used for sharing a Java `String` object. Thus, complex objects may be shared in a manner very similar to Mocha's standard Replica object. Figure 3 illustrates how both a generic Replica and derived Replica object might be used. Here, `StringReplica`, a new subclass of Replica, which is used to share a String object that has been generated by `MochaGen`. This new subclass provides the following custom constructor:

```
StringReplica replica4 = new StringReplica ("text", mocha, string, 5);
```

Note that in the application the only difference in using a derived Replica object instead of the generic Replica is the need to call the new constructor which now uses a String object for the initialization of the subclassed Replica. Figure 3 also illustrates how both types of Replicas may be accessed or modified in an almost identical fashion.

It is worth noting that more experienced Java users are permitted to replace the code that the `MochaGen` tool generates for serialization/unserialization with more optimized code when apriori knowledge regarding the use of objects is available. For example, assume a large object is being shared in which only a few number of integer variables might change value. Because only a small amount of state changes, much more efficient versions of the serialization routines are possible. Instead of serializing the whole object, more advanced routines might simply serialize/unserialize only the few integer variables that have been modified.

3 Basic Object Consistency Algorithm

The implementation of Mocha's shared object replicas utilizes a daemon thread at each site manager, and a single synchronization thread at the home site. The home site in our system is simply the site at which the initial application thread executes. All of the threads mentioned above are implemented using the standard Java threads library. All objects that the application threads wish to share are registered with the

```
public class StringReplica extends Replica {
   ...

   String string;  // A ``complex'' object that is desired to be shared

   public StringReplica (String name, Mocha mocha, String string,
                         int numcopies) {
      // This constructor used to create a shared object

      // Marshal string object into a byte array
      // Use standard Mocha methods to distribute byte array to Replicas
   }

   public StringReplica (String name, Mocha mocha) {
      // This constructor used to get a replica of a shared object

      // call superclass' constructor, i.e., super(name, mocha);
      // unserialize received byte array and place in string object;
   }

   public  void serialize() {
       // Serialize string object (using standard Java object serialization)
       // and store in Replica's byte array
       // This method will be called automatically by Mocha runtime
       // when necessary
   }

   public void unserialize() {
       // Unserialize object (using standard Java object serialization)
       // from Replica's byte array and load into string
       // This method will be called automatically by Mocha runtime
       // when necessary
   }

}
```

Figure 4: Skeleton code for a generated subclass of Mocha's Replica class to support a String object.

```
   Lock Method

if (another local thread currently has
 this lock or waiting for it)

 wait();

send synchronization thread ReplicaLockId

receive GRANT Message M from
 synchronization thread;

newVersionNumber = unpackNewVersionNumber;
versionFlag = unpackVersionFlag;

if (versionFlag == VERSIONOK)
 // We have an up-to-date version number
 // and may simply return

else
 // we must wait for new version to be sent
 receive replicas from a remote daemon;
 unpackReplicas();

return;
```

```
   Unlock Method

send synchronization thread ReplicaLockId
 and newVersionNumber of associated objects

if (another local thread currently
 is waiting for this lock)
 notify();

return;
```

Figure 5: ReplicaLock object's lock and unlock methods which are executed by application threads.

local daemon thread allowing it to directly access the shared objects themselves. The daemon threads execute at maximum priority which guarantees they may interrupt lower priority application threads when necessary. This behavior permits the daemon threads to perform the transfer of shared objects to remote sites as well to accept shared object consistency updates from remote sites when necessary. The asynchrony present in this architecture allows Mocha the flexibility to dynamically configure itself during execution from a streamlined shared object system to one that can handle common failures.

The synchronization thread handles *lock* and *unlock* requests from application threads. In addition, the synchronization thread directs daemon threads to perform operations such as transferring replicas to remote sites and is also responsible for deducing when such activities are necessary.

As described in the previous section, the Mocha shared object model consists of replicas which must be associated with a ReplicaLock object thereby supporting a variant of entry consistency[BZ91]. When an application thread desires exclusive access to shared replicas, it calls the ReplicaLock's `lock()` method. The pseudo-code for this method is provided in Figure 5. As shown in the pseudo-code, when an application thread makes this method call, if any other *local* application threads have called this method, it must first wait until their calls have completed. After waiting, the thread sends the synchronization thread a lock `REQUEST` message which contains the identifier of the desired lock. When the lock is free, the synchronization thread responds with a `GRANT` message that contains the version number of the replicas

```
while(true)  {

   Receive message M from anyone;

   if (M.type == REGISTERREPLICA) {
     // perform startup and
     // initialization activities
   }
   else if (M.type == TRANSFERREPLICA) {
     lockId = unpackLockId();

     // unpack destination information
     host   = unpackDestinationAddress();
     port   = unpackDestinationPort();

     replicaLock = replicaLockVector.find(lockId);

     replicaLock.packReplicas();

     send packed replicas to destination;
   }
}
```

Figure 6: Pseudo-code for a daemon thread.

associated with this lock and a flag which denotes whether or not a new version of the replicas need to be sent. If no new replicas need to be sent (i.e., the thread already has the most recent copy), the method may return and the application thread is free to access the replicas. If a new version of the replicas is coming, the application thread must wait for the new replicas to arrive and unmarshals them into the local copies before permitting access.

An application thread releases access to shared replicas by calling the ReplicaLock's `unlock()` method. This method call is responsible for sending the synchronization thread a message that indicates that the lock is being released. The method contains the identifier for the lock as well the updated version number associated with the replicas. Pseudo-code for this method is provided in Figure 5. Note that although it is possible that another local thread may be waiting for the lock, a local transfer is not permitted to insure lock acquisition proceeds in a manner that guarantees fairness.

The more complex aspects of Mocha's shared object support may be found in the operation of the daemon threads and the synchronization thread. Each daemon thread is responsible for startup activities such as initialization, and responding to requests regarding the transfer and acceptance of replicas. As shown in Figure 6, when a daemon thread receives a request for its copy of replicas, the thread identifies the replicas associated with the lock identifier it receives, marshals those replicas and sends them to the mandated destination.

The synchronization thread at the home node is responsible for granting locks, queuing requests, and deducing whether a new version of replicas must be sent to an application thread. Figure 7 presents pseudo-code for the synchronization thread's operations. Upon receiving a request to acquire a lock, the synchronization thread

```
while(true) {
   Receive message M from anyone;
   if (M.type == ACQUIRELOCK) {
      lockId = unpackLockId();
      if (!lockVector.exists(lockId)) {
          create new Lock object
      }

      lock1 = lockVector.find(lockId);
      if (!lock1.isFree()) {
          lock1.queueRequest();
      }
      else {
          lock1.queueRequest();
          packNewVersionNumber(lock1.returnVersionNumber());
          if (lock1.lastLockOwner() = M.source) {
              packVersionFlag(VERSIONOK);
              send GRANT message to M.source;
          }
          else {
              packVersionFlag(NEEDNEWVERSION);
              send GRANT message to M.source;
              send TRANSFERREPLICA to lock1.lastLockOwner().daemon;
          }
      }
   }
   else if (M.type == RELEASELOCK) {
      lock1 = lockVector.find(lockId);
      lock1.updateVersionNumber();
      lock1.updateDaemonId();
      //dequeue the current owner
      lockRequest = lock1.dequeueRequest();
      lock1.lastLockOwner = lockRequest.requestingHost;
      if (!lock1.isFree()) {
         nextlockRequest = lock1.examineQueueHead();
         packNewVersionNumber(lock1.returnVersionNumber());
         packVersionFlag(NEEDNEWVERSION);
         send GRANT message to nextlockRequest.source;
         send TRANSFERREPLICA to lock1.lastLockOwner().daemon;
      }
   }
}
```

Figure 7: Pseudo-code for the synchronization thread.

determines if the lock exists and creates a `Lock` object if necessary. The thread then determines if the lock is free or currently owned by another thread. If the lock is not free the request is queued. If the lock is free, the acquire request is granted by sending a `GRANT` message to the requesting thread. This message contains the new version number for the replicas as well as a flag indicating whether or not new replicas will also arrive. The synchronization thread relies on the method `lastLockOwner()` to determine the value of the flag. If new replicas need to be sent, the synchronization thread sends a message to the daemon associated with the last owner of the lock and directs it to transfer a copy of its replicas to the application thread which desires them.

When the synchronization thread receives a request to release a lock, it updates state information such as the new version number and the identifier of the daemon that now has the most recent copy. The synchronization thread then dequeues the current owner of the lock and checks to see if another lock request is queued. If another request exists, this request is granted via a `GRANT` message and the appropriate daemon thread is instructed to transfer a copy of its replicas to the application thread which desires them.

Several aspects of the basic algorithm are worth emphasizing. First, replica data is transmitted directly from one application thread address space to another application thread without having to be transmitted via the (central) synchronization thread. This allows the system to exploit locality which may exist in a wide area distributed computing environment. Second, application threads never assume that replicas will arrive but instead examine a flag to determine this aspect. This approach provides the flexibility needed to efficiently augment the basic algorithm with advanced features such as a "push-based" replication scheme that is described in the section which follows. Third, the user may notice that version numbers are being maintained however not yet used in any significant manner. Their purpose is also described in the next section. Finally, for simplicity, we described the basic algorithm assuming exclusive locks. It can easily be modified to support shared (i.e., read-only) locks.

4 Fault Tolerant Refinements

As previously discussed, we anticipate failures to be more common in wide area computing environments than traditional local area network computing environments. This has motivated us to modify Mocha's basic state sharing algorithm by incorporating fault handling refinements. The failure of a remote application thread can result in the following shortcomings in the basic algorithm. First, if an application thread which has released the lock to a shared object fails before another thread has pulled a copy of the shared object, this most recent version of the shared state will be lost. Thus, the next thread that desires a copy of this shared object will not be able to acquire this most recent version of the object. Second, if a thread which currently has acquired a lock fails, then no other thread will be permitted access to the shared object and this may result in a deadlock in the system.

The object sharing system can be enhanced to provide fault tolerance using a

number of different techniques. These include transactional support, server replication and virtual synchrony, and checkpoint/restart mechanisms. Our focus is on developing basic support that can be used to make the object sharing system robust with minimal overhead. As a result, we focus on the following two refinements:

- We detect failures of remote Mocha servers using timeouts and take appropriate actions to handle such failures (e.g., release lock held by a failed server).
- To ensure that a shared object's state is not lost because of a node failure, an application can choose to disseminate the object's state to multiple sites. Such dissemination is done to achieve high availability even when it is not required by the consistency protocol.

Our refinements are based on the assumption that the home node, where the synchronization thread executes, is less prone to failures because it is controlled by the user initiating the application. Thus, the focus is on dealing with failures of remote nodes.

Mocha allows objects to be replicated for state sharing. We also exploit the replicas to increase the probability that there is an operational thread that has an up-to-date copy of the desired objects. Support for updating multiple replicas of objects has been added in Mocha by permitting ReplicaLock objects to reconfigure themselves to employ a "push-based" update scheme. In this approach, when a thread is ready to release access to the replicas associated with a ReplicaLock, it may disseminate a copy of the replicas to a subset of threads that have registered to utilize these replicas. This is supported by having ReplicaLocks maintain state information regarding other application threads that have registered that they also desire access to the replicas. Specifically, the ReplicaLock keeps track of the daemon threads associated with these application threads. Recall that these daemon threads have access to the shared replica objects and may apply the disseminated updates directly. Assume that R is the number of such daemon threads that share the copy of an object.

Additionally, ReplicaLock objects maintain state information regarding UR, the number of up-to-date copies of the shared object. Thus, UR represents a subset of the object replicas that store the most up-to-date values of the objects. If no fault tolerance is desired, $UR = 1$ and only the node that produced the current value stores it. The new value will be sent to other nodes only when they acquire the lock associated with the object. When $UR = k$, the value will be sent to k nodes even when it is not required by the consistency protocols. The changing of R and UR (and hence the reconfiguration of the level of availability of shared objects) may be performed by either application threads or by the Mocha runtime which has access to this state information through its daemon threads.

With application threads now able to dictate the amount of update dissemination, it is necessary that the synchronization thread be cognizant of the current value of UR. This permits it to decide whether or not a new replica value must be sent to an application thread. For example, if an application thread has configured a ReplicaLock to disseminate its version of replicas to a subset of threads and one of these threads now desires access to these replicas, it is no longer necessary for

the synchronization thread to direct a daemon thread to transmit the new version because it is already there. To permit the synchronization thread to make this type of decision, the ReplicaLock's `unlock()` method has been modified to include in its lock release method a set of identifiers (i.e., a bit vector) for the daemon threads to which it has disseminated copies of the replicas. When granting the lock to next application thread that desires it, the synchronization thread consults this set to determine if the application thread requires a new copy of the replicas.

With replication support in place, it is now possible for failure resiliency to be integrated into the Mocha system. The following subsections present the modifications necessary for failure detection and handling.

Failure of Non-Lock Owning Application Thread. A failure by an application thread that does not own a lock may be detected in several ways. First, if this thread had the most up-to-date version of the replicas then the synchronization thread will contact the thread's daemon thread to perform a transfer of replicas. Assuming a fault was due either to a system crash or a local user terminating the site manager process, the daemon thread will also no longer be executing. Thus, the synchronization thread will detect the failure when the transfer message it sends to the daemon thread times out. In this particular instance, the synchronization thread handles the failure by polling other daemon threads to obtain the most recent version of the replicas available. If the new object values are disseminated to multiple nodes then in all probability (depending upon the number of failures) the most recent version of the replicas will be available and the synchronization thread may forward the replicas to requesting thread. If the values produced by the failed site were not disseminated then the synchronization thread will only receive older versions of the replicas. It can then examine version numbers to forward the most recently available old version of the replicas. This weakened consistency may be appropriate for certain classes of applications such as service to the home whereby the home user can recognize unwanted characteristics of the old version and reapply the appropriate updates to the replicas.

A second way the failure of an application thread may be detected is when another application thread utilizes the update facilities and attempts to disseminate its version to other daemon threads. Here, we again assume that the failure of an application thread implies its associated daemon thread will also fail. When attempting to disseminate the new replicas, the send message will time out. The failure has been detected and can be handled by choosing another daemon thread at another site to receive a copy of the new version of replicas.

In Mocha, we implemented fault detection and handling for this type of failure by having the synchronization thread detect failures when the transfer message it sends to a daemon thread times out. The synchronization thread then handles the failure by polling other daemon threads to obtain the most recent version of the replicas available.

Failure of Lock Owning Application Thread. Failure of an application thread that currently owns a lock is another situation that must detected and handled. This failure may be detected by having the synchronization thread timestamp lock acquisitions and having threads indicate approximately how long they need to hold a lock. The synchronization thread can periodically peruse its list of held locks to determine if any threads are holding locks for an extraordinary amount of time and therefore a candidate for being a failed thread. The synchronization thread can confirm this suspicion by sending a "heartbeat" message to the appropriate daemon thread. If this message times out the synchronization thread can assume the application thread has failed and thus the failure has been detected. Here, the synchronization thread can simply break the lock and give it to the next application thread that desires it. The most recent copy of the replicas will now be those available from daemon thread of the previous owner of the lock or if necessary the synchronization thread may resort to polling daemons for the most recent version of the replicas. Furthermore, an application thread that fails in this manner is prevented from making future requests.

In Mocha, we implemented fault detection and handling for this type of failure by having the user threads indicate how long they need to hold a lock. The synchronization thread timestamps lock acquisitions and if a lock is held for longer than expected, the synchronization thread breaks the lock and gives it to the next application thread that desires it. The next application thread to acquire the lock receives the most recent version of the replica available.

Failure of Synchronization Thread. In general, we assume the synchronization thread executes at the initial home site and therefore will be less likely to fail compared to application threads executing at remote sites. Failures that take place when a machine reboots, a task is killed by another user, or failures due to network contention are not expected to happen very frequently at the home site. This is due to the fact that in the local environment there is more control over the computing resources. Because of these reasons and to keep the overhead of failure handling low, we chose not to implement the synchronization thread in a failure resilient manner. However, we do have some ideas on how to mitigate failures of the synchronization thread. Failure detection and handling of the synchronization thread could be handled by logging its state and employing a recovery protocol whereby a new synchronization thread is spawned which informs the daemon threads of its existence. Application threads which time out attempting to contact the failed synchronization thread can query the local daemon thread to obtain the location of the newly created surrogate synchronization thread.

5 Evaluation

This section provides an evaluation of the state sharing support provided by our prototype system. We present the overheads associated with several core activities performed by the system to support object sharing. These include lock acquisition latency, data marshaling overheads, and communication overheads incurred transfer-

Local Area Network (Fast Ethernet)	5
Wide Area (Internet)	19

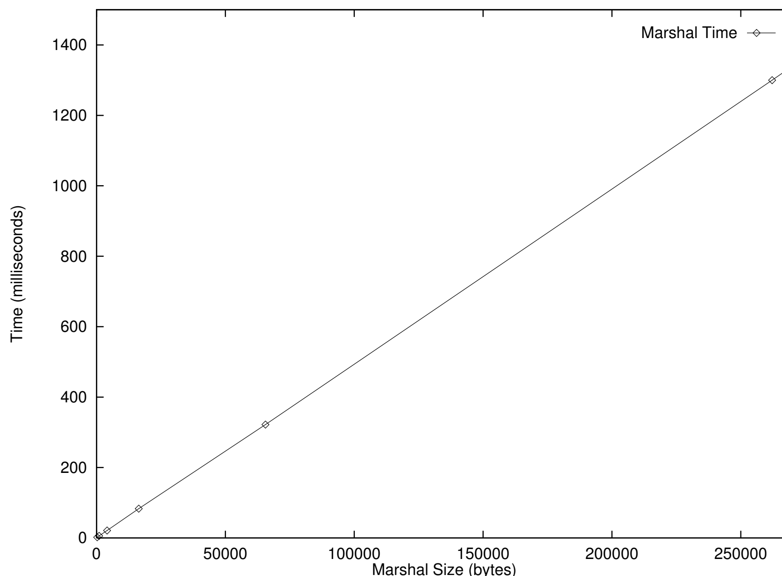

Figure 8: Time to marshal Replicas in milliseconds.

ring replicas in both a local and wide area network. This section also describes a home service application which we have implemented using the facilities provided by the system prototype.

Table 1 presents the amount of time in milliseconds to perform lock acquisition using the methods of the `ReplicaLock` object. The local area network results are from two SUN ULTRA 1 machines on Fast Ethernet. The wide area results are from a SUN ULTRA 1 and a SUN SPARCstation 20 connected via the Internet separated by a distance of approximately 6 miles. As shown in the Table, lock acquisition latency in wide area networks can be significantly greater than the latency experienced in local area networks.

Figure 8 presents the time for a SUN ULTRA 1 to marshal a replica into a byte array to enable it to be transferred over the network. As shown in the Figure, this activity can be somewhat expensive for large replicas. This inefficiency is a result of the Mocha system relying on the generic data marshaling constructs provided by Java JDK 1.1. These constructs utilize dynamic arrays and marshal a single byte at a time. These factors result in marshaling being a relatively costly operation. In the future, we plan on providing a custom marshaling library that is more efficient for our needs.

For the transfer of replicas between hosts, we have developed two separate prototype systems. In the first system, all communication is performed using Mocha's

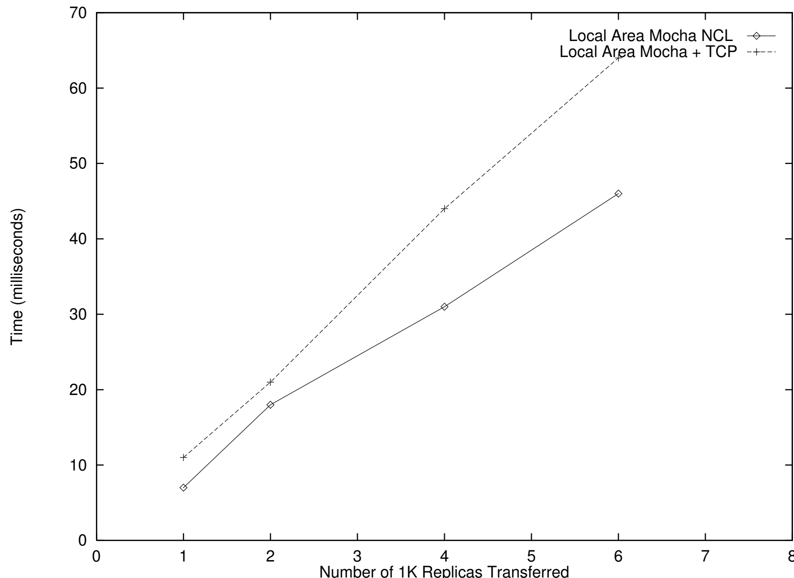

Figure 9: Time for local area transfer of 1K replicas in milliseconds.

network object library. This library implements reliable, sequenced, delivery of messages as well as performing fragmentation and reassembly. It is scalable in the number of hosts that communicate with the library because it performs its own upward multiplexing of packets. It is particularly well suited for sending small messages as it avoids the heavy connection and tear-down overheads associated with other transport protocols such as TCP. Empirically, we have found Mocha's network communication library to be approximately twice as fast as TCP for sending small (i.e., less than 256 byte) messages.

For the second prototype, small "control" messages used for lock acquisition and directing data transfers are sent using Mocha's network object library. For the actual transfer of replica data which typically involves sending large messages, we have developed a "hybrid protocol" approach whereby Mocha's custom network object library is used in conjunction with TCP. Here, Mocha's network communication is used for establishing a TCP connection (i.e., propagating TCP port numbers) and the actual transfer of replica data is done using TCP. Figure 9 presents the times in milliseconds to disseminate a 1K replica to several local area network hosts and Figure 10 illustrates the same dissemination of replicas for wide area networks. In both environments, solely using Mocha's network communication library is the more efficient approach. This is attributable to the higher connection and tear-down overheads associated with the hybrid approach.

As we increase the size of the replicas, the hybrid protocol approach provided by the second prototype begins to perform much better than simply using Mocha's network communication library for both local and wide area networks. These results are presented in Figures 11 and 12 for 4K replica transfers in local area networks and wide area networks respectively. Furthermore, as shown in Figures 13 and 14, for larger replicas reaching sizes of 256K the superiority of the hybrid protocol becomes

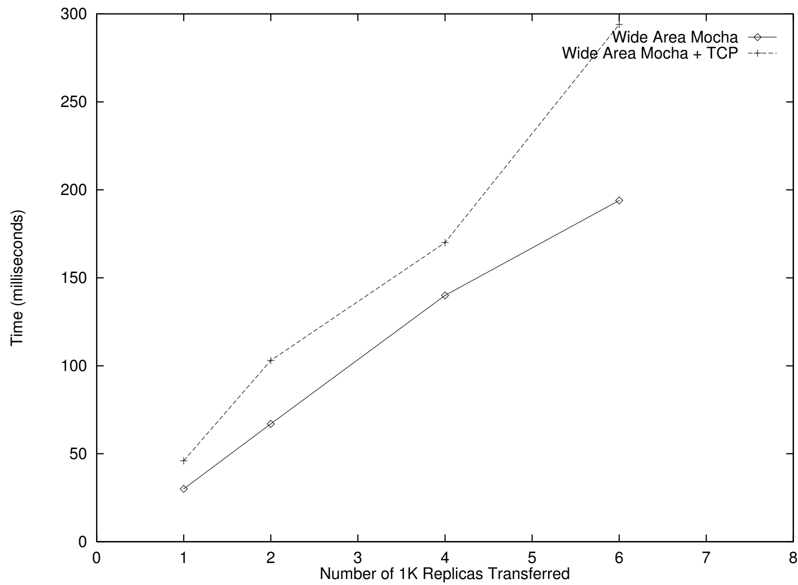

Figure 10: Time for wide area transfer of 1K replicas in milliseconds.

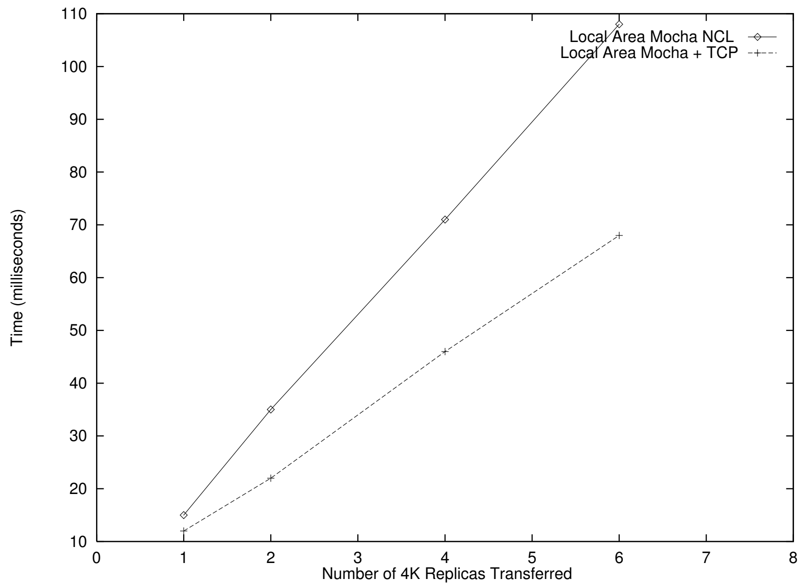

Figure 11: Time for local area transfer of 4K replicas in milliseconds.

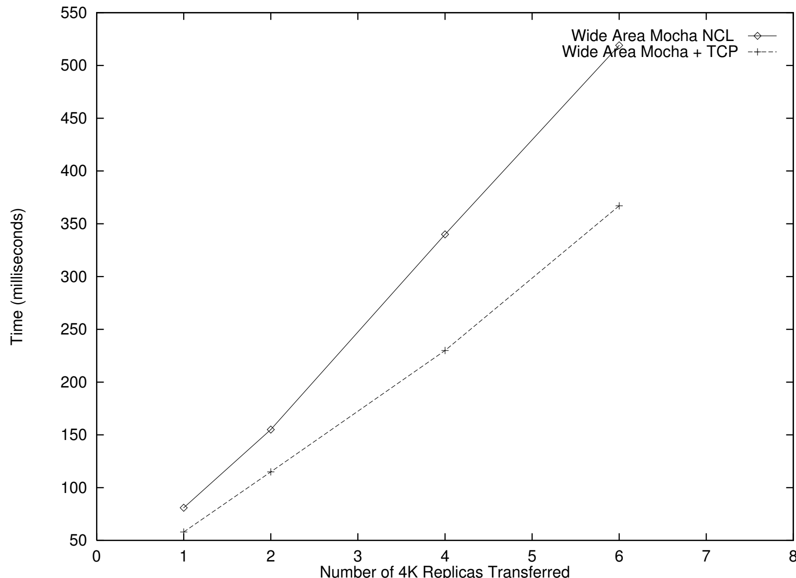

Figure 12: Time for wide area transfer of 4K replicas in milliseconds.

clear. This vast improvement is attributable to the speeds at which both protocols perform fragmentation and reassembly. Mocha's fragmentation and assembly executes at user level running as interpreted byte code. The TCP fragmentation and reassembly executes as native binary code at the kernel level. This vast disparity of execution speeds allows TCP to easily ameliorate its connection and tear-down overheads for large, multipacket messages.

In summary, several aspects regarding the cost of update dissemination for high availability as well as the relative efficiency of the two approaches for transferring replicas are apparent. As can be seen from Figure 12, when the number of moderately sized (i.e., 4K) replicas that are maintained up-to-date in a wide area environment is increased from 1 to 2, the overhead for consistency maintenance approximately doubles. Furthermore, as also depicted in Figure 12, the hybrid protocol approach can result in an improvement of approximately 30% over Mocha's basic protocol for transferring replicas as small as 4K to multiple (i.e., 6) sites. As shown in Figure 14, for replicas as large as 256K, the hybrid protocol can reduce transfer costs by as much as 70% over the basic protocol when transferring replicas to multiple sites in a wide area environment.

5.1 Applications

We are exploring a range of applications that can run on Mocha. Here, we describe one such application. Figure 15 presents a sample home service application written with the Mocha system. The application is a formal dinner table setting coordinator application similar to the one described in Section 2. In this application, the GUI shown in Figure 15 is sent via Mocha's remote evaluation support to execute at several remote sites. Each site may modify the flatware, plates, or glassware currently

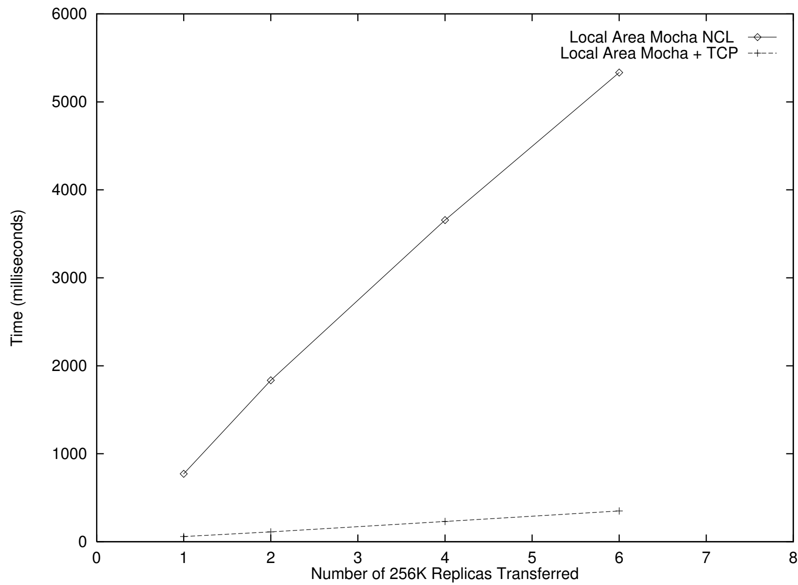

Figure 13: Time for local area transfer of 256K replicas in milliseconds.

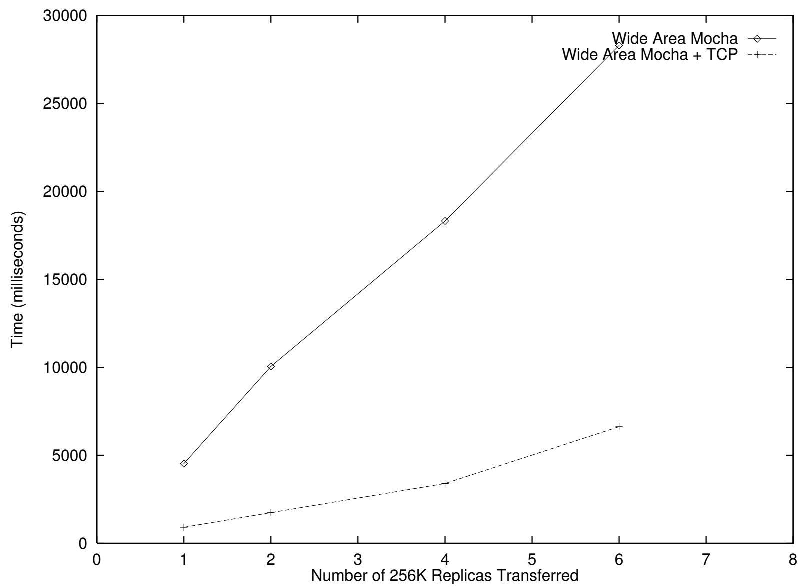

Figure 14: Time for wide area transfer of 256K replicas in milliseconds.

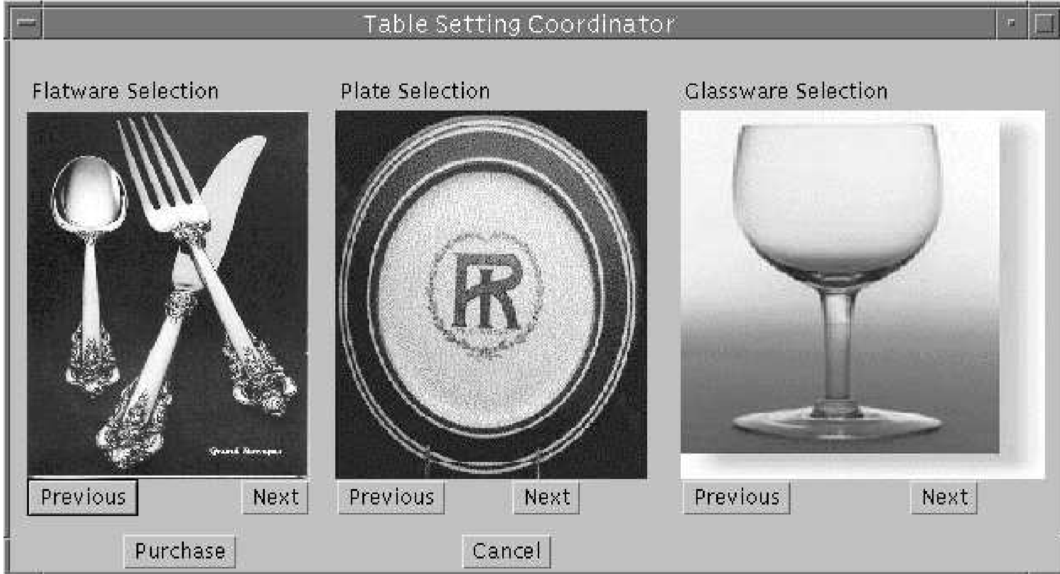

Figure 15: Mocha Table Setting Coordinator Home Service Application.

being displayed by pushing the appropriate `previous` or `next` button. These buttons result in activating callbacks which modify shared index variables associated with each item. A thread which executes in each remote GUI periodically polls the shared index variables for new values and updates the local display as needed. The graphical images are also shared as replicas but are not associated with a `ReplicaLock`. Thus, they are cached at each host without any consistency maintenance being performed on them. The shared indexes do however rely on the system's consistency maintenance facilities.

Empirically, we have measured the marshaling, lock acquisition, and transfer costs of keeping these three replicas consistent in a wide area environment. Marshaling required 3 milliseconds, lock acquisition overhead was 19 milliseconds and transfer costs were measured at 44 milliseconds. Overall, the total cost of maintaining consistency is 66 milliseconds, a latency value that we feel is suitable for this type of application.

6 Related Work

Mocha's goals as well as the techniques employed by it are related to several research areas. These include metacomputing systems, DSM systems, and systems that address fault-tolerance. We describe systems from each of these categories.

Wide area computing is closely related to metacomputing. A number of metacomputing systems are currently being implemented. Some systems rely on message passing instead of shared objects to allow tasks to cooperate. Examples of these systems include Chandy's worldwide distributed system[C+96] and IceT[GS97]. For the Mocha system, we chose to utilize shared objects instead of message passing because they provide a model that is simpler to program than standard message passing. Furthermore, we provide replicated copies for failure handling which in a message passing

model would require group communication and virtual synchrony support[B+91] and is not currently addressed by the above message passing systems.

Another non-shared object approach utilized by metacomputing systems to allow task cooperation is the use of remote procedure call (RPC) or its object-based equivalent, remote method invocation (RMI). Atlas[BBB96], WebWork[F+95], NetSolve[CD96], and Legion[GW96] all rely on forms of RPC/RMI for task interaction. In some cases, a RPC/RMI model's performance suffers from the clients need to repeatedly contact a server to perform distributed computation. This of course depends on the type of remote computing activities being performed as well as the type of caching strategies employed by the RPC/RMI system. For a more thorough comparison of RPC/RMI and shared memory please refer to [YC97].

Several metacomputing systems are currently providing shared memory. The TIE design[CMRB96] supports shared objects via object caching and entry consistency. The developers of TIE believe that in the future, available network bandwidth will be limited (due to growing popularity of the internet) and aggressive caching must be performed to avoid server bottlenecks. The TIE design is in some ways similar to Mocha but the emphasis of the two systems is quite different. the TIE system currently focuses on mobile objects and security while Mocha focuses on high availability and advanced support for sharing general purpose Java objects. We are also not aware of an implementation of TIE.

The ParaWeb system[BHST96] modifies the Java interpreter to provide a global shared address space using distributed shared memory techniques pioneered by systems such as Munin and Treadmarks. In the ParaWeb implementation, the Java interpreters have been modified to permit them to cooperate and maintain the illusion of global shared memory. ParaWeb utilizes Java's built-in synchronization facilities to monitor when remote memory must be updated to maintain the illusion of consistent global memory. In a similar approach, Yu and Cox[YC97] are currently implementing a parallel Java Virtual Machine layered on top of the TreadMarks page-based distributed shared memory system. Currently, they are addressing problems such as data type conversion between machines of different architectures as well as garbage collection. Mocha's approach towards supporting shared state differs from these two systems as it supports it at the object level while these systems support sharing at the page level. The difference in the two approaches results in the need to solve different types of problems. With the shared sequence of bytes approach, these systems typically must modify the Java virtual machine, must compensate for different byte orderings in heterogeneous environments, and mitigate false sharing. Although Mocha's shared object approach does not encounter these types of problems, it must deal with issues such as how to support complex objects.

Java Shared Data API (JSDA)[Jsd97] provides shared variable support using its own multipoint data delivery service. With JSDA, an update to a shared variable is sent to a session server which then sends the update to other threads that are sharing the variable. In contrast, the Mocha system attempts to exploit locality by sending shared state changes directly to the next thread that needs access to the data. Mocha also allows the number of updated replicas to be configured whereas JSDA updates all copies.

PageSpace[CT96] relies on a Linda-like coordination technology. Essentially, PageSpace supports a global tuple space which nodes may insert or remove tuples without any regard for where the tuples are stored.

Mocha's consistency actions are driven by synchronization operations. In certain systems and applications, synchronization for all operations may not be desirable. For example, systems such as Bayou[TDP+94], Coda[KS92], and Rover[J+95] which address mobility avoid synchronization and instead rely upon conflict detection and resolution to maintain consistency. Our future work will explore non-synchronization based consistency models that are suitable for supporting shared objects.

In summary, Mocha's state sharing support distinguishes itself from the above systems by combining advanced distributed shared object techniques with failure handling support that allows its overheads to be controlled based upon the level of availability needed for shared objects. Additionally, Mocha's runtime exploits Java's method overriding and serialization capabilities to support the sharing of complex objects without requiring modifications to the standard Java interpreter. Moreover, we have a broad application focus including applications directed to the home.

7 Conclusions

In this article, we have presented a robust shared object model for wide area distributed applications that has been implemented as part of the Mocha wide area computing infrastructure we are currently developing. Our model provides support for shared objects on heterogeneous platforms, and utilizes advanced distributed memory techniques for maintaining consistency of shared objects. Moreover, our system provides fault tolerance support that allows its overhead to be controlled based on the level of availability needed by an application. We have investigated a combination of protocols approach for improving the efficiency of shared state transfer between hosts and performed an empirical evaluation of two versions of our prototype system in both local and wide area networks.

Currently, we are focusing on providing support for applications which require non-synchronization based solutions for maintaining consistency. We have also begun evaluating the system in a more accurate home service environment, namely, a Windows 95 PC connected via a cable modem to a Unix workstation. Future work will focus on the development of a larger application base as well as visualization support to provide greater insight into the execution of wide area distributed applications.
